A Unified Modeling Framework to Abstract Knowledge of Dynamically Adaptive Systems

Ludovic Mouline

April 24, 2019

Abstract

Vision: As state-of-the-art techniques fail to model efficiently the evolution and the uncertainty existing in dynamically adaptive systems, the adaptation process makes suboptimal decisions. To tackle this challenge, modern modeling frameworks should efficiently encapsulate time and uncertainty as first-class concepts.

Context Smart grid approach introduces information and communication technologies into traditional power grid to cope with new challenges of electricity distribution. Among them, one challenge is the resiliency of the grid: how to automatically recover from any incident such as overload? These systems therefore need a deep understanding of the ongoing situation which enables reasoning tasks for healing operations. **Abstraction** is a key technique that provided an illuminating description of systems, their behaviors, and/or their environments alleviating their complexity. **Adaptation** is a cornerstone feature that enables reconfiguration at runtime for optimizing software to the current and/or future situation.

Abstraction technique is pushed to its paramountcy by the model-driven engineering (MDE) methodology. However, information concerning the grid, such as loads, is not always known with absolute confidence. Through the thesis, this lack of confidence about data is referred to as **data uncertainty**. They are approximated from the measured consumption and the grid topology. This topology is inferred from fuse states, which are set by technicians after their services on the grid. As humans are not error-free, the topology is therefore not known with absolute confidence. This data uncertainty is propagated to the load through the computation made. If it is neither present in the model nor not considered by the adaptation process, then the adaptation

process may make suboptimal reconfiguration decision.

The literature refers to systems which provide adaptation capabilities as dynamically adaptive systems (DAS). One challenge in the grid is the phase difference between the monitoring frequency and the time for actions to have measurable effects. Action with no immediate measurable effects are named **delayed action**. On the one hand, an incident should be detected in the next minutes. On the other hand, a reconfiguration action can take up to several hours. For example, when a tree falls on a cable and cuts it during a storm, the grid manager should be noticed in real time. The reconfiguration of the grid, to reconnect as many people as possible before replacing the cable, is done by technicians who need to use their cars to go on the reconfiguration places. In a fully autonomous adaptive system, the reasoning process should be considered the ongoing actions to avoid repeating decisions.

Problematic **Data uncertainty and delayed actions are not specific to smart grids.**

First, data are, almost by definition, uncertain and developers always work with estimates. Hardware sensors have by construction a precision that can vary according to the current environment in which they are deployed. A simple example is the temperature sensor that provides a temperature with precision to the nearest degree. Software sensors approximate also values from these physical sensors, which increases the uncertainty. For example, CPU usage is computed counting the cycle used by a program. As stated by Intel, this counter is not error-prone[1].

Second, it always exists a delay between the moment where a suboptimal state is detected by the adaptation process and the moment where the effects of decisions taken are measured. This delayed is due to the time needed by a computer to process data and, eventually, to send orders or data through networks. For example, migrating a virtual machine from a server to another one can take several minutes.

Through this thesis, I argue that this data uncertainty and this delay cannot be ignored for all dynamic adaptive systems. To know if the data uncertainty should be considered, stakeholders should wonder **if this data uncertainty**

[1] https://software.intel.com/en-us/itc-user-and-reference-guide-cpu-cycle-counter

affects the result of their reasoning process, like adaptation. Regarding delayed action, they should verify **if the frequency of the monitoring stage is lower than the time of action effects to be measurable**. These characteristics are common to smart grids, cloud infrastructure or cyber-physical systems in general.

Challenge These problematics come with different challenges concerning the representation of the knowledge for DAS. The global challenge address by this thesis is: **how to represent the uncertain knowledge allowing to efficiently query it and to represent ongoing actions in order to improve adaptation processes?**

Vision **This thesis defends the need for a unified modeling framework which includes, despite all traditional elements, temporal and uncertainty as first-class concepts.** Therefore, a developer will be able to abstract information related to the adaptation process, the environment as well as the system itself.

Concerning the adaptation process, the framework should enable abstraction of the actions, their context, their impact, and the specification of this process (requirements and constraints). It should also enable the abstraction of the system environment and its behavior. Finally, the framework should represent the structure, behavior and specification of the system itself as well as the actuators and sensors. All these representations should integrate the data uncertainty existing.

Contributions Towards this vision, this document presents two approaches: a temporal context model and a language for uncertain data.

The temporal context model allows abstracting past, ongoing and future actions with their impacts and context. First, a developer can use this model to know what the ongoing actions, with their expect future impacts on the system, are. Second, she/he can navigate through past decisions to understand why they have been made when they have led to a sub-optimal state.

The language, named Ain'tea, integrates data uncertainty as a first-class concept. It allows developers to attach data with a probability distribution which represents their uncertainty. Plus, it mapped all arithmetic and boolean operators to uncertainty propagation operations. And so, developers will automatically propagate the uncertainty

of data without additional effort, compared to an algorithm which manipulates certain data.

Validation Each contribution has been evaluated separately. The language has been evaluated through two axes: its ability to detect errors at development time and its expressiveness. Ain'tea can detect errors in the combination of uncertain data earlier than state-of-the-art approaches. The language is also as expressive as current approaches found in the literature. Moreover, we use this language to implement the load approximation of a smart grid furnished by an industrial partner, Creos S.A.[2].

The context model has been evaluated through the performance axis. The dissertation shows that it can be used to represent the Luxembourg smart grid. The model also provides an API which enables the execution of query for diagnosis purpose. In order to show the feasibility of the solution, it has also been applied to the use case provided by the industrial partner.

Abstract: *Model-driven engineering methodology and dynamically adaptive systems approach are combined to tackle new challenges brought by systems nowadays. After introducing these two software engineering techniques, I give one example of such systems: the Luxembourg smart grid. I will also use this example to highlight two of the problematics: uncertainty of data and delays in actions. Among the different challenges which are implied by them, I present the global one addressed by the vision defended in this thesis: modeling of temporal and uncertain data. This global challenge can be addressed by splitting up in several ones. I present two of them, which are directly tackled by two contributions presented in this thesis.*

Abstract: *Adaptation processes are executed with a high frequency to react to any incidents whereas the execution of their decisions is constrained by the executions of delayed actions. We identified two problems that result from these different paces. First, unfinished actions, together with their expected effects, over time are not considered, leading upcoming analysis phases potentially make suboptimal decisions. Second, explanation of the adaptation process remains challenging due to the lack of tracing ability of current approaches. To tackle this problem, we first propose a knowledge formalism to define the concept of a decision. Second, we describe a novel temporal knowledge model to represent, store and query decisions as well as their relationship with the knowledge*

(context, requirements, and actions). We validate our approach through a use case based on the smart grid at Luxembourg. We also demonstrate its scalability both in terms of execution time and consumed memory.

Introduction

Adaptive systems have proven their suitability to handle the increasing complexity of system and their ever-changing environment. To do so, they make adaptation decisions, in the form of actions, based on high-level policies. For instance, the OpenStack Watcher project [Tea15] implements a MAPE-k loop to assist cloud administrators in their activities to tune and rebalance their cloud resources according to some optimization goals (e.g., CPU and network bandwidth). For readability purpose, we refer to adaptation decision as decision in the remaining part of this document.

Despite the reactivity of adaptation processes, impacts of their decisions can be measurable long after they have been taken. We identified two problematics caused by this difference of paces:

- How to reason over unfinished actions and their expected effects?
- How to diagnose the self-adaptation process?

To address them, we propose a temporal knowledge model which can trace its decisions over time, along with their circumstances and effects. By storing them, the adaptation process could consider the ongoing actions with their expected effects. Plus, in case of faulty decisions, developers may trace back their effects to their circumstances.

The rest of this chapter is structured as follows. In the remaining part of this section, we motivate our approach, we summarize core concepts manipulated in adaptation processes, and we present a use case scenario based on the Luxembourg Smart Grid (*cf.* Chapter *TODO*: **add ref**). Then, we provide a formal definition of these concepts in Section 2.2. Later, we describe the proposed data model in Section 2.3. In Section 2.4, we demonstrate the applicability of our approach by applying it to the smart grid example. We conclude this chapter in Section 2.5.

Motivation

Delayed action

In this section we will motivate the need to reason over delayed actions. To do so, we will first give four examples of these actions in Section 2.1.2. Section 2.1.2 detail why the effects of actions should be considered. In Section **??** we summarise and motivate

the need for incorporating actions and their effect in the knowledge.

Delayed action examples

Until here, we claim that adaptation process should handle delayed actions. In order to show their existence, we will give four different examples: two from our use case, one from cloud infrastructures and one from smart homes. From our understanding, three phenomena can explain this delay: the time to execute the action (*cf.* Example 1), the time for the system to handle the new configuration (*cf.* Example 3) and the inertia of the measured element (*cf.* Example 2 and 4).

Example 1: Modification of fuse states in smart grids Even if the Luxembourg power grid is moving to an autonomous one, not all the elements can be remotely controlled. One example is the fuses, they still need to me open or close by a human. In this document, open and close actions in the smart grid imply technicians who are contacted, drive to fuses places and manually change fuse states. If several fuses need to be changed, one technician may have to drive to them, sequentially, and executes the modifications. For example, in our case our industrial partner asks us to consider that each fuse modification should take in average 15 min whereas any incident should be detected in the minute. Let's imagine that an incident is detected at 4p.m. and can be solved by modifying three fuses. Before the incident will be marked as resolved, $15min * 3 = 45min$. The incidents will be seen as resolved by the adaptation process at 4:45p.m. In summary, the delay of the action is due to the execution time that is not immediate.

Example 2: Reduction of amps limit in smart grids[1] In his smart grid project, Creos envisages controlling remotely amps limits of the grid users. Specific plugs will be furnished to them, which will allow them managing what can be controlled and what cannot be. One example of those is plugs to load electric vehicles. However, due to how power consumption is measured by meters, and even if the action is near instant, the impacts of the action would not be visible immediately. Indeed, data received by Creos corresponds to the total energy consumed since the installation. From this information,

[1]This example is based on randomly generated data. As this action is not yet available on the Luxembourg smart grid, we miss real data. However, it reflects an hypothesis shared with our partner.

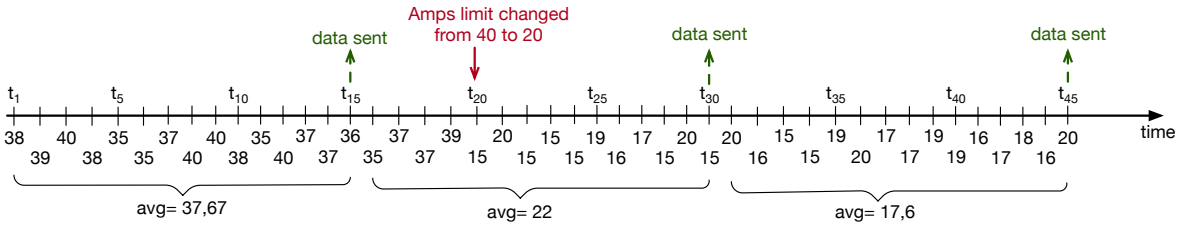

Figure 2.1: Example of consumption measurement before and after a limitation of amps has been executed at t_{20}.

only the average of consumed data for the last period can be computed.

In Figure 2.1, we depict a scenario that shows the delay between the action is executed and the impacts are measured. Each timepoint represents one minute, with the consumption at this moment.

Let's imagine a customer who has his or her limit set to 40 amps[2] and consume near this limit. We consider that data are sent every 15 min. After receiving data sent at t_{15} and processing them, the adaptation process detects an overload and decides to reduce the limits to 20 amps for the customer. However, considering the delay for data to be collected and the one to sent data[3], the order is received and executed at t_{20}. At t_30, new data consumption are sent, here equal to 22 amps. Here there is two situations. First, this reduction was enough to fix the overload. Even in this idealistic scenario, the adaptation process should wait at worst 15min (t_{30} - t_{15}) to see the resolution (without considering the communication time). Second, this reduction was not enough - as the adaptation process considered that the consumption data will be at worst 20 amps and here it is 22. Before seeing the incident as solved, the adaptation process should wait new data, sent at t_{45}. It should wait around 30min ($t_{45} - t_{15}$) for this.

In summary, the delay of this action can be explained by the inertia in the consumption measurement.

Example 3: Switching off a machine from a load balancer An example in cloud infrastructure of long actions is to remove a machine from a load balancer, for example during a scale down operation. Scale down operation allows cloud manager to

[2]It means that the user cannot consume more than 40 amps at a precise time t_i.
[3]Reminder: the smart grid is not built upon a fast network such a fiber network.

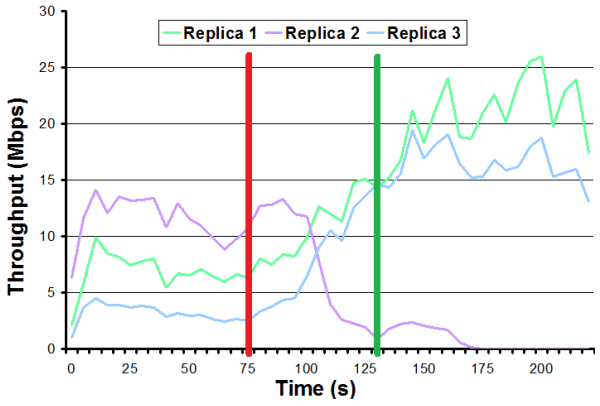

Figure 2.2: Figure extracted from [WBR11] that shows the delay between the time where the machine Replica 2 (R2) stop receiving new connections to prepare its disconnection (depicted by the red bar), effective around 100s later. The green bar represents the moment where the all the rules in the load balancer stop considering R2.

reduce allocated resources for a specific case. It is used either to reduce the cost of the infrastructure or to reallocate them to other tasks. In [WBR11], Wang *et al.,* present a load-balancing algorithm. In their evaluation, they present the figure depicted in Figure 2.2 that show the evolution of the throughput after the server Replica 2 (R2) is removing from the load balancer. The red bars shows the moment where stop receiving new connection and the green one shows the moment where it is removed from the load balancer algorithm. However, despite these actions have been taken, R2 should finish the ongoing tasks that it is executing. This explain why the throughout is progressively decreasing to 0 and there is a delay of around 100s between the red bars and the moment where is a no connection.

This example shows a delayed action due to the time required by the system to handle the new configuration.

Example 4: Modifying home temperature through a smart home system Smart home systems have been implemented in order to remotely manage a house or to automatically perform routines. For example, it allows users to close or open blinds from their smartphones from anyplace, even outside the house. The temperature can be automatically manage by such systems, for example given targeted temperature at

precise time. However, heating or cooling a house is not immediate, it can take several hours before the targeted temperature is reached. Plus, if the temperature sensor and the heating or cooling system or not placed nearby, the new temperature can take time before being measured. This can be explained due to the temperature inertia plus the delay for the temperature to be propagated.

Through these four examples, we show that delayed actions can be found in different kind of systems, from CPS to cloud infrastructure. However, not only knowing that an action is running is important but also knowing its expecting effect. We detail this point in the next section.

The need to consider effects

In the previous section we show the existence of delayed actions. One may argue that action status is already integrated in the knowledge. For example, the OpenStack Watcher framework stores them in a data base [4], accessible through an API. However, for the best of our knowledge Watcher does not store the expecting effects of each action. While the adaptation process knows what action is running, it does not know what it should expect from them.

Considering our example based on the modification of fuses, if the system knows that the technician is modifying fuse states, it may not know what would be the effects. In this case, when the adaptation process analyses the system context it may wonder: what will be the next grid configuration? how the load will be balanced? will the future configuration fix all the current incidents? If the effects are not considered by the adaptation process, then it may take suboptimal decisions.

Let's exemplify this claim through a scenario based on the modification of fuses example. At t_0 an overload in one cable is detected and the state of three fuses need to be modified. As explained in the previous section, this will take around 45 min. We consider that the system can mark a incident as "being resolved". In the knowledge, two informations are therefore stored: the fact the the overload incident is being resolved and the fact it is done by modifying three fuses. However, during the resolution stage, another cable is overloading. With these informations, the system can either wait the

[4] https://docs.openstack.org/watcher/latest/glossary.html#watcher-database-definition

end of the resolution of the first incident to see if both overloads will be fix or it take other actions without considering the ongoing actions. Applying the first strategy may make the resolution of the second incident late, whereas the second one may generate suboptimal sequence of actions. For example, the second modifications may undo what have been done before or both actions may be conflicting.

Conclusion

Actions, like fuse modification in a smart grid or removing a server from a load balancer, generated during by adaptation proecess could take time upon completion. Moreover, the expected effects resulting from such action is reflected in the context representation only after a certain delay. One used workaround is the selection, often empirically, of an optimistic time interval between two iterations of the MAPE-K loop such that this interval is bigger than the longest action execution time. However, the time to execute an action is highly influenced by system overload or failures, making such empirical tuning barely reliable. We argue that by enriching context representation with support for past and future planned actions and their expected effects over time, we can highly enhance reasoning processes and avoid empirical tuning.

Fined and rich context information directly influences the accuracy of the actions taken. Various techniques to represent context information have been proposed; among which we find the models@run.time [**?**]. The models@run.time paradigm inherits model-driven engineering concepts to extend the use of models not only at design time but also at runtime. This model-based representation has proven its ability to structure complex systems and synthesize its internal state as well as its surrounding environment.

In this thesis, we propose therefore a meta-model of the knowledge which include action and their effects. Our current approach is limited to the representation of measurable effects of any action.

Diagnosis support

Background

Use case scenario

Knowledge formalization

As discussed previously, I consider knowledge to be the association of context information, requirements, and action information, all in one global and unified model. While context information captures the state of the system environment and its surroundings, the system requirements define the constraints that the system should satisfy along the way. The actions, on the other hand, are means to reach the goals of the system.

In this section, I provide a formalization of the knowledge used by adaptation processes based on a temporal graph. Indeed, due to the complexity and interconnectivity of system entities, graph data representation seems to be an appropriate way to represent the knowledge. Augmented with a temporal dimension, temporal graphs are then able to symbolize the evolution of system entities and states over time. We benefit from the well-defined graph manipulation operations, namely temporal graph pattern matching and temporal graph relations to represent the traceability links between the decisions made and their circumstances.

Before describing this formalism, I describe the semantic used for the temporal axis. Then, I exemplify the knowledge formalism using the Luxembourg smart grid use case.

Formalization of the temporal axis

The formalism describe below has been made with two goals in mind. First, the definition of the time space should allow the distinction between past and future. Doing this distinction enable the differentiation between measured data and estimated (or predicted data). Second, it should permit the definition of the life cycle of an element of the knowledge, which can be seen as a succession of states with a validity period that should not overlap each other.

Time space T is considered as an ordered discrete set of time points non-uniformly

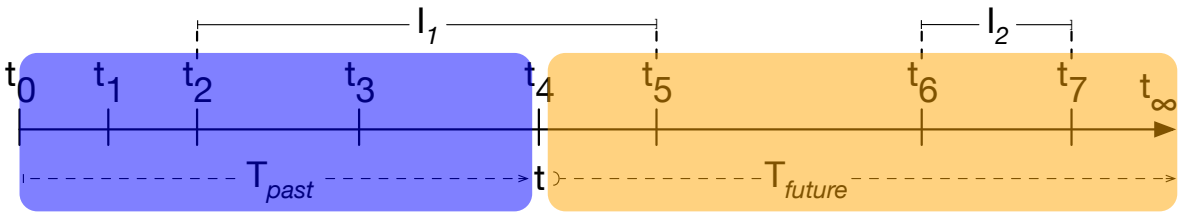

Figure 2.3: Time definition used for the knowledge formalism

distributed. As depicted in Figure 2.3, this set can be divided into 3 different subsets $T = T_{past} \cup \{t\} \cup T_{future}$, where:

- T_{past} is the sub-domain $\{t_0;t_1;\ldots;t_{current-1}\}$ representing graph data history starting from t_0, the oldest point, until current time, t, excluded.
- $\{t\}$ is a singleton representing the current time point
- T_{future} is sub-domain $\{t_{current+1};\ldots;t_\infty\}$ representing future time points

The three domains depend completely on the current time $\{t\}$ as these subsets slide as time passes. At any point in time, these domains never overlap: $T_{past} \cap \{t\} = \emptyset$, $T_{future} \cap \{t\} = \emptyset$, and $T_{past} \cap T_{future} = \emptyset$. The definition of these three subsets reachs the first goal.

In addition, there is a right-opened time interval $I \in T \times T$ as $[t_s, t_e)$ where $t_e - t_s > 0$. In English words, it means that the interval cannot represent a single time point and should follow the time order. For any $i \in I$, $start(i)$ denotes its lower bound and $end(i)$ its upper bound. As detailed in Section **??**, these intervals are used to define the validity period for each node of the graph.

Figure 2.3 displays an example of a time space $T_1 = \{t_0, t_1, t_2, t_3, t_4, t_5, t_6, t_7\}$. Here, the current time is $t = t_4$. According to the definition of the past subset (T_{past}) and the future one (T_{future}), there is: $T_{past1} = \{t_0, t_1, t_2, t_3\}$ and $T_{future1} = \{t_5, t_6, t_7\}$. Two intervals have been defined on T_1, namely I_1 and I_2. The first one starts at t_2 and ends at t_5 and the last one is defined from t_6 to t_7. As shown with I_1, an interval could be defined on different subsets, here it is on all of them (T_{past}, t, and T_{future}).

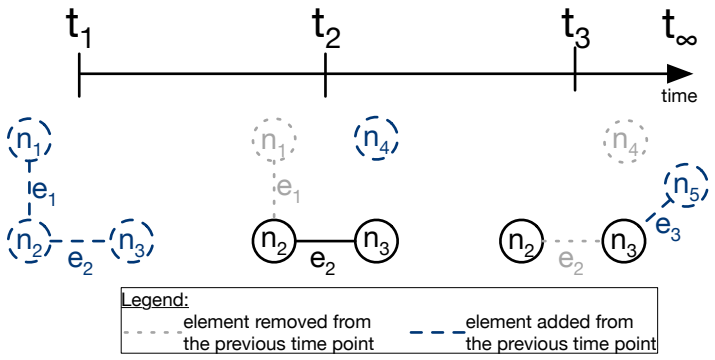

Figure 2.4: Evolution of a temporal graph over time

Formalism

Graph definition First, let K be an adaptive process over a system knowledge represented by a graph such as $K = (N, E)$, comprising a set of nodes N and a set of edges E. Nodes represent any element of the knowledge (context, actions, *etc.*) and edges represent their relationships. Nodes have a set of attribute values. An attribute value has a type (numerical, boolean, ...). Every relationship $e \in E$ can be considered as a couple of nodes $(n_s, n_t) \in N \times N$, where n_s is the source node and n_t is the target node.

Adding the temporal dimension In order to augment the graph with a temporal dimension, the relation V^T is added. So now the knowledge K is defined as a temporal graph such as $K = (N, E, V^T)$.

A node is considered valid either until it is removed or until one of its attributes value changes. In the latter case, a new node with the updated value is created. Whilst, an edge is considered valid until either its source node and target node is valid, or until the edge itself is removed. Otherwise, nodes and edges are considered invalid. The temporal validity relation is defined as $V^T : N \cup E \rightarrow I$. It takes as a parameter a node or an edge ($k \in N \cup E$) and returns a time interval ($i \in I$, *cf.* Section 2.2.1) during which the graph element is valid.

Figure 2.4 shows an example of a temporal graph K_1 with five nodes (n_1, n_2,n_3, n_4, and n_5) and three edges (e_1, e_2, and e_3) over a lifecycle from t_1 to t_3. In this

way, K_1 equals to $(\{n_1, n_2, n_3, n_4, n_5\}, \{e_1, e_2, e_3\}, V_1^T)$. Let's assume that the graph is created at t_1. As n_1 is modified at t_2, its validity period starts at t_1 and ends at t_2: $V_1^T(n_1) = [t_1, t_2)$. n_2 and n_3 are not modified; their validity period thus starts at t_1 and ends at t_∞: $V_1^T(n_2) = V_1^T(n_3) = [t_1, t_\infty)$. Regarding the edges, the first one, e_1, is between n_1 and n_2 and the second one, e_2 from n_2 to n_3. Both are created at t_1. As n_1 is being modified at t_2, its validity period goes from t_1 to t_2: $V_1^T(e_1) = [t_1, t_2)$. e_2 is deleted at t_3. Its validity period is thus equal to: $V_1^T(e_2) = [t_1, t_3)$.

Lifecycle of a knowledge element One node represents the state of exactly one knowledge element during a period named the validity period. The lifecycle of a knowledge element is thus modeled by a unique set of nodes. By definition, the validity periods of the different nodes cannot overlap. A same time period cannot be represented by two different nodes, which could create inconsistency in the temporal graph.

To keep track of this knowledge element history, the Z^T relation is added to the graph formalism: $K = (N, E, V^T, Z^T)$. It serves to trace the updates of a given knowledge element at any point in time. This relation can also be seen as a temporal identity function which takes as parameters a given node $n \in N$ and a specific time point $t \in T$, and returns the corresponding node at that point. Formally, $Z^T : N \times T \to N$.

In order to consider this new relation in the example presented in Figure 2.4, the definition of K_1 is modified to $K_1 = (\{n_1, n_2, n_3, n_4, n_5\}, \{e_1, e_2, e_3\}, V_1^T, Z_1^T)$ In Figure 2.4, let's imagine that n_1, n_4, and n_5 represent the same knowledge element k_e. The lifecycle of k_e is thus:

- n_1 for period $[t_1, t_2)$,
- n_4 for period $[t_2, t_3)$,
- n_5 for period $[t_3, t_\infty)$.

Let t_1' be a timepoint between t_1 and t_2. When one wants to resolve the node representing the knowledge element at t_1', she or he gets n_1 node, no matter of the node input (n_1, n_4, or n_5): $Z_1^T(n_4, t_1) = n_1$. On the other hand, applying the same relation with another node (n_2 or n_3) returns another node. For example, if n_2 and n_3 do not belongs to the same knowledge element, then it will return the node given as input, for example $Z_1^T(n_2, t_1) = n_2$.

Knowledge elements stored in nodes Nodes are used to store the different knowledge elements: context, requirements and actions. The set of nodes N is thus split in three subset: $N = C \cup R \cup A$ where C is the set of nodes which store context information, R a set of nodes for requirement information and A the set of nodes for actions information.

Actions define a process that indirectly impact the context: they will change the behavior of the system, which will be reflected on the context information. Requirements are also processes that are continuously run over the system in order to check the specifications. Here, the purpose of the A and R subset is not to store these processes but to list them. It can be thought as a catalogue of actions and requirements, with their history.

Using a high level overview, these processes can the depicted as: taking the knowledge as input, perform task, and modify this knowledge as output. As detailed in the next two paragraphs, they can be formalized by relations.

Temporal queries for requirements At the current state, the formalism of the knowledge K do not contain any information regarding the requirement processes. To overcome this, system requirements processes R_P are added such as $K = (N, E, V^T, Z^T, R_P)$. R_P is a set of patterns $P_{[t_j,t_k]}(K)$ and queries Q over these patterns: $R_P = P \cup Q$.

$P_{[t_j,t_k]}$ denotes a temporal graph pattern, where t_j and t_k are the lower and upper bound of the time interval respectively. The time interval can be either fixed (absolute) or sliding (relative). Each element of the pattern should be valid for at least one time point: $\forall\ p \in P_{[t_j,t_k)}, V^T(e) \cap [t_j, t_k) \neq \emptyset$. Patterns can be seen as temporal subgraph of K, with a time limiting constraint coming in the form of a time interval. Temporal graph queries Q consist commonly of two parts: (i) path description to traverse the graph nodes, at both structural and temporal dimensions; (ii) arithmetic expressions on nodes, edges, and attribute values.

Temporal relations for actions Like for R_P, the knowledge K needs to be augmented with the action processes A_P: $K = (N, E, V^T, Z^T, R_P, A_P)$. Actions processes A_P can be regarded as a set of relations or isomorphisms mapping a source temporal graph pattern $P_{[t_j,t_k]}$ to a target one $P_{[t_l,t_m]}$, $A_P : K \times I \rightarrow K \times I$.

The left-hand side of the relation depicts the temporal graph elements over which an action is applied. Every relation may have a set of application conditions. They describe the circumstances under which an action should take place. These application conditions are either positive, should hold, or negative, should not hold. Application conditions come in the form of temporal graph invariants. The side effects of these actions are represented by the right-hand side.

Finally, we associate to A_P a temporal function E_{A_P} to determine the time interval at which an action has been executed. Formally, $X : A \rightarrow I$.

Temporal relations for decisions Finally, the knowledge formalism needs to include the last, but not the least, element: decisions made by the adaptation, $K = (N, E, V^T, Z^T, R_P, A_P, D)$ While the source of relations in D represents the state before the execution of an action, the target shows its impact on the context. Its intent is **to trace back impacts of actions execution to the decisions they originated from**.

A decision present in D is defined as a set of executed actions, *i.e.,* a subset of A_P. Formally, $D = \{\ A_D \cup R_D \mid A_D \subseteq A_P, R_D \subseteq R_P\}$. We assume that each action should result from one decision: $\forall a \in A, \forall d1, d2 \in D \mid a \in d1 \wedge a \in d2 \rightarrow d1 = d2$.

The temporal function E_{A_P} is extended to decision in order to represent the execution time: $E_{A_P} : (A \cup D) \rightarrow I$. For decision, the lower bound of the interval correspond to the lowest bound of the action execution intervals. Following the same principle, the upper bound of the interval correspond to the uppermost bound of the action execution intervals. Formally, $\forall d \in D \rightarrow E_{A_P}(d) = [l, u)$, where $l = \min_{a \in A_d}\{E_{A_P}(a)[start]\}$ and $u = \max_{a \in A_d}\{E_{A_P}(a)[end]\}$.

Sum up Knowledge of an adaptive system can be formalism with a temporal graph such as $K = (N, E, V^T, Z^T, R_P, A_P, D)$, wherein:

- N is a set of nodes to represent the different information (context, actions and requirements)
- E is a set of edges with connect the different nodes,
- V^T is a temporal relation which defines the temporal validity of each elements,
- Z^T is a relation to track the history of each knowledge elements,

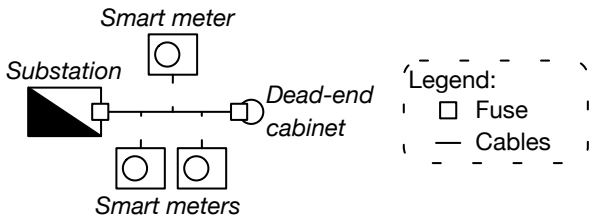

Figure 2.5: Simplified version of a smart grid

Figure 2.6: Representation of the smart grid context depicted in Figure 2.5

- R_P is a relation that define the different requirements processes,
- A_P is a relation that define the different action processes,
- D is a set of action processes that result from a same decision.

In the next section, we exemplify this formalism over our case study.

Application on the use case

The example presented in Section 1.2 contain too much detail to provide a readable and understandable example of the formalism. Below, an excerpt of it is thus presented in order to overcome this problem.

Excerpt of a smart grid Figure 2.5 shows a simplified version of a smart grid with one substation, one cable, three smart meters and one dead-end cabinet. Both the substation and the cabinet have a fuse. The meters regularly send consumption data at the same time. One requirement is considered for this example: minimizing the number of overloads. To achieve so, among the different actions, two actions are taken into account in this example: decreasing or increasing the amps limits of smart meters.

Let K_{SG} be the temporal graph that represents the knowledge of this adaptive system: $K_{SG} = (N_{SG}, E_{SG}, V^T_{SG}, Z^T_{SG}, R_{P_{SG}}, A_{P_{SG}}, D_{SG})$. Figure 2.6 shows the nodes and edges of this knowledge.

Scenario The system starts at t_0 with the actions, the requirements and the context, which also include initial value for the consumption values. Meters send their values at t_2 and t_3. Based on these data, the load on cables and substation is computed. On t_2,

an overload is detected on the cable, which break the requirement. At the same time point, the system decides to reduce the load of all smart meters. The impact of these actions will be measured at t_4, *i.e.,* the cable will not be overloaded from t_4.

Description of N_{SG} N_{SG} is divided into three subset: C_{SG}, R_{SG} and A_{SG}. R_{SG} contains one node, R_1 in Figure 2.6, which represents the requirement of this example: $R_{SG} = \{R_1\}$ Two nodes, A_1 and A_2, belong to A_{SG}: $A_{SG} = \{A_1, A_2\}$. They represent represent the two actions of this example, respectively decreasing and increasing amps limits. Regarding the context C_{SG}, there is three nodes to represent the three smart meters (M_1, M_2, and M_3), one for the substation (S_1), two for the fuses (F_1 and F_2), one for the dead-end cabinet (D_{C_1}) and one node per consumption value received (V_i): $C_{SG} = \{M_1, M_2, M_3, S_1, F_1, F_2, D_{C_1}\} \cup \{V_i | i \in [1..9]\}$.

According to the scenario, all nodes are created at t_0 and are never modified, except for nodes to store consumption values. Therefore, their validity period starts at t_0 and never ends: $\forall n \in A_{SG} \cup R_{SG} \cup \{M_1, M_2, M_3, S_1, F_1, F_2, D_{C_1}\}, V^T_{SG}(n) = [t_0, t_\infty)$. Considering the consumption values, all the nodes represent the history of the values for the three smart meters. In other words, there is three knowledge element: the consumption measured for each meter. Let C_i notes the consumption measured by the smart meter M_i. As shown in Figure 2.6, there is:

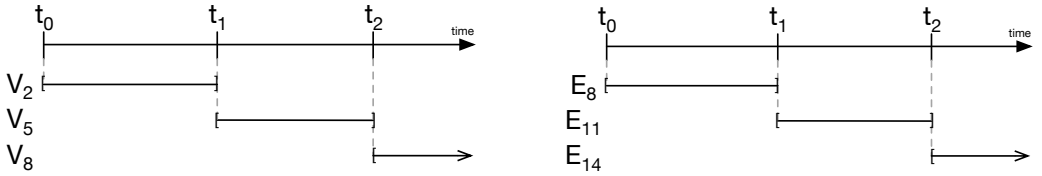
- C_1 of M_1 is represented by $\{V_1, V_4, V_7\}$,
- C_2 of M_2 is represented by $\{V_2, V_5, V_8\}$,
- C_3 of M_3 is represented by $\{V_3, V_5, V_9\}$.

Taking C_2 as example, V_2 is the initial consumption value, replaced by V_5 at t_1, itself replaced by V_8 at t_2. Applying the V^T_{SG} on these different values, results are thus:

- $V^T_{SG}(V_2) = [t_0, t_1)$,
- $V^T_{SG}(V_5) = [t_1, t_2)$,
- $V^T_{SG}(V_8) = [t_2, t_\infty)$.

These validity periods are shown in Figure 2.7a. As meters send the new consumption values at the same time, this example can be also applied to C_1 and C_3.

From these validity period, the Z^T_{SG} can be used to navigate to the different values over time. Let's continue with the same example, C_2. In order to get the evolution of



(a) Consumption values (b) Edges

Figure 2.7: Validity periods of the consumptions values and their edges to the smart meter M_2

the consumption value C_2, given the initial one, one will use the Z^T_{SG} relation:

- $Z^T_{SG}(V_2, t_{s1}) = V_2$, where $t_0 \leqslant t_{s1} < t_1$
- $Z^T_{SG}(V_2, t_{s2}) = V_5$, where $t_1 \leqslant t_{s2} < t_2$
- $Z^T_{SG}(V_2, t_{s3}) = V_8$, where $t_2 \leqslant t_{s3} < t_\infty$.

Description of E_{SG} In this example, edges are used to store the relationships between the different context elements. For example, the edge between the substation S_1 and the fuse F_1 allow to represent the fact that the fuse is physically inside the substation. Another example, edges between the cable C_1 and the meters M_1, M_2 and M_3 represent the fact that these meters are connected to the smart grid through this cable.

One may consider that relations (validity, Z^T, decisions, action processes and requirements processes) will be stored as edges. But, this decision is let to the implementation part of this formalism.

In our model, only consumption values (V_i nodes) are modified. Plus, since the scenario do not imply other edges modifications, only those between meters and values are modified. The edge set contains thus sixteen edges: $E_{SG} = \{E_i \mid i \in [1..16]\}$.

By definition, the unmodified edges have a validity period starting from t_0 and never ends: $\forall i \in [1..7], V^T_{SG}(E_i) = [t_0, t\infty)$. The history of the three knowledge elements that represent consumption values do not only impact the nodes which represent the values but also the edges between those nodes and the meters ones:

- C_1 impacts edges between M_1 and V_1, V_4, and V_7, *i.e.,* $\{E_8, E_{11}, E_{14}\}$,
- C_2 impacts edges between M_2 and V_2, V_5, and V_8, *i.e.,* $\{E_9, E_{12}, E_{15}\}$,
- C_3 impacts edges between M_3 and V_3, V_6, and V_9, *i.e.,* $\{E_{10}, E_{13}, E_{16}\}$.

Continuing with C_2 as example, the initial edge value is E_8 from t_0, which is replaced by E_{11} from t_1, itself replaced by E_{14} from t_2. The validity relation, applied on these edges, thus returns:

- $V^T_{SG}(E_8) = [t_0, t_1) = V^T_{SG}(V_2)$,
- $V^T_{SG}(E_{11}) = [t_1, t_2) = V^T_{SG}(V_5)$,
- $V^T_{SG}(E_{14}) = [t_2, t_\infty) = V^T_{SG}(V_8)$,

These validity periods are depicted in Figure 2.7b. As they are driven by those of consumption values (V_2, V_5, and V_8), they are equals.

As for nodes, the Z^T_{SG} relation can navigate over time through these values. For example, to get the history of the edges between the consumption value C_2 and the meter represented by M_2, one can apply the Z^T_{SG} relation as following:

- $Z^T_{SG}(E_8, t_{s1}) = E_8$, where $t_0 \leqslant t_{s1} < t_1$,
- $Z^T_{SG}(E_8, t_{s2}) = E_8$, where $t_1 \leqslant t_{s1} < t_2$,
- $Z^T_{SG}(E_8, t_{s3}) = E_8$, where $t_2 \leqslant t_{s1} < t_\infty$.

Description of $R_{P_{SG}}$ The requirement calls for minimizing overloads. It means that when the system detects at least one overload, for example in cables, it will take counter actions. As the system has prediction capabilities, it will not only check is there is one at the current time t but also if one will come in the next hour. The pattern will be defined as follow: $P_{[t,t+15min]}$. To determine if there is an overload, the system needs to know: the current and future consumption, the current and future topology. The last one is used to compute the loads from the consumption (cf. Section 1.2).

Let's consider that time points are regular and there is one every 15 minutes and that current time is t_0. The pattern, $P_{[t_0,t_1]}$, will thus contain all nodes that are valid between t_0 and t_1 (included):

- all topology nodes between: $\{S_1, C_1, F_1, F_2, D_{C_1}, M_1, M_2, M_3\}$
- all consumption values between: $\{V_i \mid i \in [1..6]\}$,
- all edges that connected these nodes: $\{E_i \mid i \in [1..13]\}$

From these values, the loads is computed and the system checks that none will exceed the capacity of the infrastructure (cables, substations, cabinets).

Description of $A_{P_{SG}}$ Now, let us assume that the execution of $R_{P_{SG}}$ detects an overload on the cable (C_1) at t_0. The system decides to reduce the amps limits, and thus the load, on the three meters. The action A_1 (decreasing amps limits) is thus executed three times: one time per meter. For each of these action, the input context will correspond to the pattern used by the requirement relation: $P_{[t_0,t_1]}$. The output context will contain the predicted values after the actions have been executed. Here, the actions are executed in parallel and their execution time is in seconds. So the impact will be visible from t_1. So the output pattern contain the three values at t_1: $P_{[t_1,t_1]}$. In summary:

- Action 1: $A_{P_1} : P_{[t_0,t_1]} \rightarrow P_{[t_1,t_1]}$,
- Action 1: $A_{P_2} : P_{[t_0,t_1]} \rightarrow P_{[t_1,t_1]}$,
- Action 1: $A_{P_3} : P_{[t_0,t_1]} \rightarrow P_{[t_1,t_1]}$.

Description of D_{SG} Following the scenario, there is one decision, D_{SG_1}, which try to achieve the requirement R_1 by executing the actions A_1: A_{P_1}, A_{P_2}, and A_{P_3}. Then, here the decision is equals to: $D_{SG_1} = \{R_1, A_{P_1}, A_{P_2}, A_{P_3}\}$.

Summrarize Through this section, I explifyed how the formalism can be used to define an adaptation decision on a smart grid system. As the decision contains information about the circumstances and the impact, one may use it to debug the process and/or try to explain the behavior of such systems.

Modeling the knowledge

In order to simplify the diagnosis of adaptive systems, this thesis proposes a novel metamodel that combines, what I call, design elements and runtime elements. Design elements abstract the different elements involved in knowledge information to assist the specification of the adaptation process. Runtime elements instead, represent the data collected by the adaptation process during its execution. In order to maintain the consistency between previous design elements and newly created ones, instances of design elements (*e.g.,* actions) can be either added or removed. Modifying these elements would consist in removing existing elements and creating new ones. Combining design elements and runtime elements in the same model helps not only to acquire

the evolution of system but also the evolution of its structure and specification (e.g. evolution of the requirements of the system). Design time elements are depicted in gray in the Figures 2.8– 2.11. Note that, this thesis does not address how runtime information is collected.

For the sake of modularity, the metamodel has been split into four packages: Knowledge, Context, Requirement and Action. All the classes of these packages have a common parent class that adds the temporality dimention: *TimedElement* class. Before describing the Knowledge (core) package, I detail this element. Then, I introduce in more details the other three packages used by the Knowledge package: Context, Requirement, and Action. In below sections, I use "*Package::Class*" notation to refer to the provenance of a class. If the package is omitted, then the provenance package is this one described by the figure or text.

Parent element: *TimedElement* class

I assume that all the classes in the different packages extend a *TimedElement* class. This class contains three methods: *startTime*, *endTime*, and *modificationsTime*. The first two methods allow accessing the validity interval bounds defined by the previously discussed V^T relation. The last method resolves all the timestamps at which an element has been modified: its history. This method is the implementation of the relation Z^T described in our formalism (cf. Section **??**).

Knowledge metamodel

In order to enable interactive diagnosis of adaptive systems, traceability links between the decisions made and their circumstances should be organized in a well-structured representation. In what follows, I introduce how the knowledge metamodel helps to describe decisions, which are linked to their goals and their context (input and impact). Figure 2.8 depicts this metamodel.

Knowledge package is composed of a *context*, a set of *requirements*, a set of *strategies*, and a set of *decisions*. A decision can be seen as the output of the Analyze and Plan steps in the Monitor, Analyze, Plan, and Execute over knowledge (MAPE-k) loop.

Decisions comprise target *goals* and trigger the execution of one *tactic* or more.

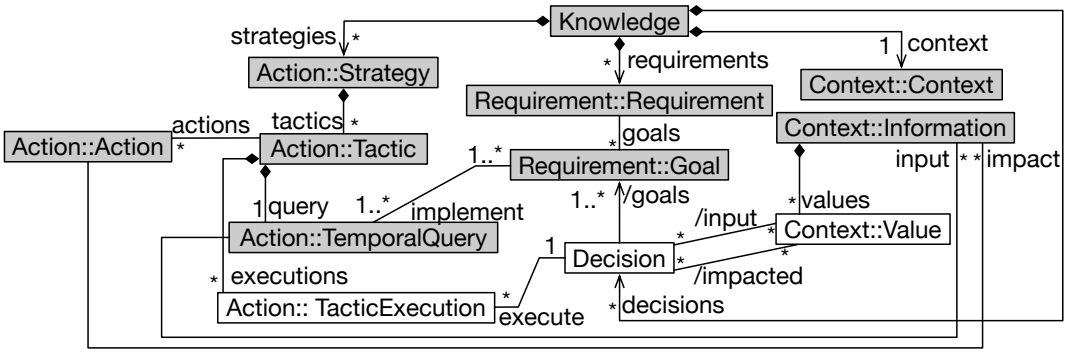


Figure 2.8: Excerpt of the knowledge metamodel

A decision has an *input* context and an *impacted* context. The context impacted by a decision (*Decision.impacted*) is a derived relationship computed by aggregating the impacts of all actions belonging to a decision (see Fig. 2.11). Likewise, the *input* relationship is derived and can be computed similarly. In the smart grid example, a decision can be formulated (in plain English) as follows: since the district D is almost overloaded (*input context*), we reduce the amps limit of greedy consumers using the "*reduce amps limit*" *action* in order to reduce the load on the cable of the district (*impact*) and satisfy the "*no overload*" policy (*requirement*).

As all the elements inherit from the *TimedElement*, we can capture the time at which a given decision and its subsequent actions were executed, and when their impact materialized, *i.e.,* measured. Thanks to this metamodel representation, a developer can apprehend the possible causes behind malicious behavior by navigating from the context values to the decisions that have impacted its value (*Property.expected.impact*) and the goals it was trying to reach (*Decision.goals*). In Section *TODO*: **add reference** , we present an example of interactive diagnosis queries applied to the smart grid use case.

Context metamodel

Context models structure context information acquired at runtime. For example, in a smart-grid system, the context model would contain information about smart-grid users (address, names, etc.) resource consumption, etc.

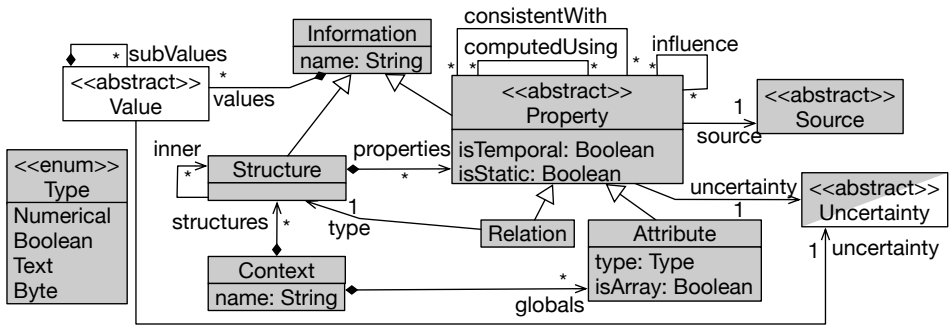

Figure 2.9: Excerpt of the context metamodel

An excerpt of the context model is depicted in Figure 2.9. I propose to represent the context as a set of structures (*Context.structures*) and global attributes (*Context.globals*). A structure can be viewed as a C-structure with a set of properties (*Property*): attributes (*Attribute*) or relationships (*Relation*). A structure may contain other nested structures (*Structure.inner*). Structures and properties have values. They correspond to the nodes described in the formalization section (*cf.* Section **??**). The connection feature described in Section **??** is represented thanks to three recursive relationships on the Property class: *consistentWith*, *computedUsing* and *influence*. Additionally, each property has a source (*Source*) and an uncertainty (*Uncertainty*). It is up to the stakeholder to extend data with the appropriate source: measured, computed, provided by a user, or by another system (*e.g.,* weather information coming from a public API). Similarly, the uncertainty class can be extended to represent the different kinds of uncertainties. Finally, a property can be either historic or static.

Requirement metamodel

As different solutions to model system requirements exist (*e.g.,* KAOS [**?**], i* [**?**] or Tropos [**?**]), in this metamodel, we abstract their shared concepts. The requirement model, depicted in Figure 2.10, represents the *requirement* as a set of *goals*. Each goal has a *nature* and a textual specification. The nature of the goals adheres to the four categories of requirements presented in Section **??**. One may use one of the existing requirements modeling languages (*e.g.,* RELAX) to define the semantics of the

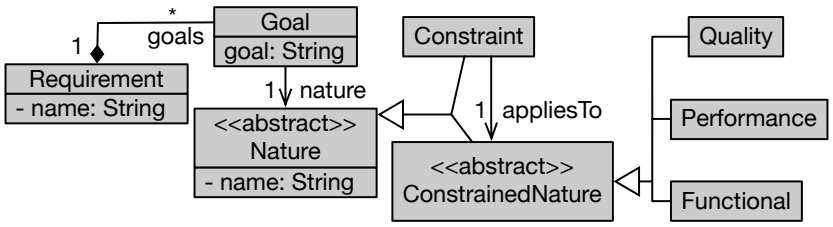

Figure 2.10: Requirement metamodel

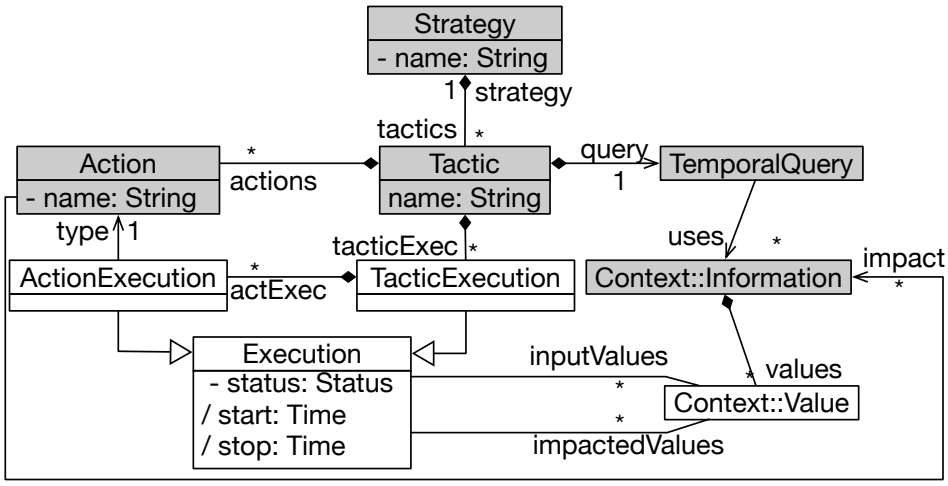

Figure 2.11: Excerpt of the action metamodel

requirements. Since the requirement model is composed solely of design elements, we may rely on static analysis techniques to infer the requirement model from existing specifications. The work of Egyed [**?**] is one solution among others. This work is out of the scope of the paper and envisaged for future work.

In the guidance example, the requirement model may contain a **balanced resource distribution** requirement. It can be split into different goals: (i) *no overload*, (ii) *no production lack*, (iii) *no production loss*.

Action metamodel

Similar to the requirements metamodel, the actions metamodel also abstracts main concepts shared among existing solutions to describe adaptation processes and how

they are linked to the context. Figure 2.11 depicts an excerpt of the action metamodel. I define a strategy as a set of tactics (*Strategy*). A tactic contains a set of actions (*Action*). A tactic is executed under a precondition represented as a temporal query (*TemporalQuery*) and uses different data from the context as input. In future work, we will investigate the use of preconditions to schedule the executions order of the actions, similarly to existing formalisms such as Stitch [**?**]. The query can be as complex as needed and can navigate through the whole knowledge model. Actions have impacts on certain properties, represented by the *impacted* reference.

The different executions are represented thanks to the *Execution* class. Each execution has a status to track its progress and links to the impacted context values(*Execution.impactedValues*). Similarly, input values are represented thanks to the *Execution.inputValues* relationship. An execution has *start* and *end* time. Not to confuse with the *startTime* and *endTime* of the validity relation $\mathcal{V}^T$. Whilst the former corresponds to the time range in which a value is valid, the *start* and *stop* time in the class execution correspond to the time range in which an action or a tactic was being executed. The start and stop attributes correspond to the relation $\mathcal{X}$ (see Section **??**). These values can be derived based on the validity relation. They correspond to the time range in which the status of the execution is "*RUNNING*". Formally, for every execution node e, $\mathcal{X}(e) = (\mathcal{V}(e) \mid e.status = \text{"RUNNING"})$.

Similarly to requirement models, it is possible to automatically infer design elements of action models by statically analyzing actions specification. Since acquiring information about tactics and actions executions happens at runtime, one way to achieve this is by intercepting calls to actions executions and updating the appropriate action model elements accordingly. This is out of the scope of this paper and planned for future work.
